

INDUCTION SEALING DEVICE AND METHOD WHICH MAY BE USED FOR
PRODUCING PACKAGES OF POURABLE FOOD PRODUCTS

10 TECHNICAL FIELD

The present invention relates to an induction sealing device and method which may be used for producing packages of pourable food products.

15 In particular, the invention may be used preferably, though not exclusively, in a form-and-seal unit for forming and sealing packages from a tube of sheet packaging material filled continuously with a pourable product.

20 BACKGROUND ART

As is known, many pourable food products (e.g. fruit or vegetable juice, pasteurized or UHT (ultra-high-temperature-treated) milk, wine, etc.) are sold in packages made of sterilized packaging material.

25 A typical example of this type of package is the parallelepiped-shaped package for pourable food products known as Tetra Brik Aseptic®, which is made by folding and sealing a web of laminated packaging material.

The laminated packaging material comprises layers of

fibrous material, e.g. paper, covered on both sides with heat-seal plastic material, e.g. polyethylene, and, in the case of aseptic packages for long-storage products, such as UHT milk, also comprises, on the side eventually 5 contacting the food product in the package, a layer of oxygen-barrier material, e.g. a sheet of aluminium or EVOH, which in turn is covered with one or more layers of heat-seal plastic material.

As is known, such packages are produced on fully 10 automatic packaging machines, on which a continuous tube is formed from the web-fed packaging material; the web of packaging material is sterilized on the packaging machine itself, e.g. by applying a chemical sterilizing agent, such as a hydrogen peroxide solution, which, once 15 sterilization is completed, is removed, e.g. vapourized by heating, from the surfaces of the packaging material; and the web of packaging material so sterilized is kept in a closed, sterile environment, and is folded and sealed longitudinally to form a vertical tube.

20 The tube is then filled from the top with the sterilized or sterile-processed pourable food product, and is gripped at equally spaced transverse sections by two pairs of jaws. More specifically, the pairs of jaws act cyclically and successively on the tube to seal the 25 packaging material of the tube and form a continuous strip of pillow packs connected to one another by respective transverse sealing bands.

The pillow packs are separated by cutting the

relative sealing bands, and are then conveyed to a final folding station where they are folded mechanically into the finished parallelepiped shape.

In the case of aseptic packages with an aluminium 5 layer as the barrier material, the transverse sections of the tube are normally sealed using a sealing device for inducing a parasitic electric current in the aluminium layer to melt the heat-seal plastic material locally.

More specifically, one of the jaws in each pair 10 comprises a main body made of non-conducting material, and an inductor housed in a front seat on the main body; and the other jaw has pressure pads made of elastically yielding material, such as rubber.

The inductor is powered when the relative pair of 15 jaws is gripped onto the tube, so as to seal a transverse section of the tube by sealing the plastic material covering.

More specifically, in addition to the inductor, the sealing device also comprises an alternating power signal 20 generator, and a matching circuit for optimizing power transfer between the generator and inductor. The generator, in fact, supplies maximum power when the current-voltage phase angle is close to zero.

Known matching circuits are normally defined by an 25 inductive-capacitive circuit, in which a capacitive element (normally defined by a number of parallel capacitors) is connected parallel to an inductive element (normally defined by a transformer); and the capacitance

values of the capacitive element, and the inductance value of the inductive element are so selected as to produce phasing whereby the current-voltage phase angle is close to zero. Such phasing, however, is best for a 5 predetermined electric load associated with given operating conditions (e.g. package volume, filling machine output rate and operating speed, type of inductor, etc.).

Consequently, alongside a variation in electric load 10 caused by varying operating conditions, there is a noticeable departure from the optimum phasing condition, thus reducing power transfer to the inductor.

DISCLOSURE OF INVENTION

It is an object of the present invention to provide 15 a sealing device designed to eliminate the drawbacks of known devices.

According to the present invention, there is provided an induction sealing device which may be used for producing packages of pourable food products by 20 transversely sealing a tube of sheet packaging material comprising at least one layer of induction-heatable material covered with plastic material, said sealing device comprising: generating means for generating an alternating power signal $S(\omega)$; at least one inductor 25 receiving the alternating power signal $S(\omega)$ to induce a parasitic electric current in said layer and locally melt said plastic material to form a transverse seal; and a matching circuit for achieving optimum power transfer

between said generator and said inductor; characterized in that said matching circuit comprises an inductive-capacitive circuit, in which at least one inductive element is connected to at least one variable-capacitance 5 capacitive element; the capacitance of the capacitive element being adjustable so that the current-voltage phase angle is close to zero.

The present invention also relates to an induction sealing method which may be used for producing packages 10 of pourable food products by transversely sealing a tube of sheet packaging material comprising at least one layer of induction-heatable material covered with plastic material, said method comprising the steps of: generating an alternating power signal $s(\omega)$; supplying said 15 alternating power signal $s(\omega)$ to at least one inductor to induce a parasitic electric current in said layer and locally melt said plastic material to form a transverse seal; and optimizing power transfer between said generator and said inductor by means of a matching 20 circuit; characterized in that said optimizing step comprises the steps of adjusting the capacitance of at least one capacitive element connected to at least one inductive element so that the current-voltage phase angle is close to zero.

25

BRIEF DESCRIPTION OF THE DRAWINGS

A preferred, non-limiting embodiment of the invention will be described by way of example with reference to the accompanying drawings, in which:

Figure 1 shows a simplified electric diagram of an induction sealing device which may be used for producing packages of pourable food products;

Figure 2 shows a portion of the Figure 1 device in 5 more detail;

Figure 3 shows a variation of the Figure 1 device.

BEST MODE FOR CARRYING OUT THE INVENTION

Number 1 in Figure 1 indicates as a whole an induction sealing device which may be used for producing 10 packages of pourable food products.

More specifically, sealing device 1 comprises a generator 3 for generating an alternating power signal $S(\omega)$; an inductor 4 which receives alternating power signal $S(\omega)$; and a matching circuit 7 for optimizing 15 power transfer between generator 3 and inductor 4.

More specifically, generator 3 may conveniently generate a variable-voltage (e.g. sinusoidal) signal of medium frequency (e.g. 530 kHz) with a peak voltage of around a few hundred (e.g. 540) volts, may generate a 20 continuous or pulsed alternating power signal $S(\omega)$, and supplies maximum power (e.g. 2500 watts) when the phase angle between the current and voltage (both measured at the output of generator 3) is close to zero.

Inductor 4 is conveniently defined by a winding 10 25 which receives alternating power signal $S(\omega)$ to generate a pulsating magnetic field which in turn produces a parasitic electric current in an aluminium sheet 12 forming part of a vertical tube 13 (shown partly and not

to scale) made from an appropriately shaped web of laminated packaging material.

The laminated packaging material comprises a central layer 15 of fibrous material (e.g. paper) covered on both 5 sides with a heat-seal plastic material 16, e.g. polyethylene; aluminium sheet 12 is interposed between the central layer 15 of fibrous material and one of the layers of plastic material 16; and the parasitic current locally melts the plastic material 16 of two contacting 10 portions of vertical tube 13 to seal tube 13 transversely.

Matching circuit 7 comprises at least one first capacitor 20 interposed between a first and a second electric line 21, 22; and a number of capacitors 24, 25, 15 26, 27 (four in the example shown, but which may obviously be of any other number) connectable/disconnectable to/from electric lines 21, 22 on the basis of control signals acting on respective switches 24a, 25a, 26a, 27a. Capacitor 20 may 20 conveniently be defined by a number of parallel capacitors (e.g. three - not shown), and may conveniently have a capacitance of around 14-40 nF.

More specifically, first ends 21a, 22a of electric lines 21, 22 define the input of matching circuit 7, and 25 second ends 21b, 22b of electric lines 21, 22 are connected to the end terminals of a primary winding 23a of a transformer 23 having a secondary winding 23b defining an output of matching circuit 7. Transformer 23

preferably has a ferrite core, and windings 23a, 23b made of Litz conductors to greatly reduce internal losses.

Matching circuit 7 therefore defines an inductive-capacitive circuit comprising an inductive element 5 (defined by winding 23a of transformer 23) parallel to a capacitive element of variable capacitance which is modified by connecting one or more capacitors 24, 25, 27, 27 parallel to capacitor 20.

According to the present invention, the capacitance 10 value of the capacitive element is regulated so that the current-voltage phase angle is close to zero.

The capacitance is conveniently regulated by a control circuit 30 which measures parameters (e.g. the instantaneous value of the current-voltage phase angle 15 ϕ at the output of generator 3 and/or the impedance at the output of generator 3, i.e. the input impedance of matching circuit 7) during the package production process, and determines the target capacitance C_{tar} the capacitance element must have to obtain a current-voltage 20 phase angle close to zero. The current and voltage are measured at the output of generator 3 by a known instrument (not shown) which measures the instantaneous values of voltage V , current I , and phase angle ϕ .

A control signal is thus sent to one or more 25 switches 24a, 25a, 26a, 27a to connect one or more capacitors 24, 25, 26, 27 parallel to capacitor 20 and achieve the determined target capacitance C_{tar} . Variations in operating conditions therefore vary the

parameters supplied to control circuit 30, which opens/closes a predetermined combination of switches 24a, 25a, 26a, 27a, so that the total capacitance satisfies the above condition.

5 Figure 2 shows an example embodiment of one of switches 24a-27a. More specifically, each of switches 24a-27a comprises a first and a second IGBT transistor 40a, 40b having emitters (E) connected to each other, and collectors (C) connected respectively to electric line 21
10 and to an end terminal of respective capacitor 24-27. The gates (G) of IGBT transistors 40a, 40b are connected to each other by an electric line 42 which, via a resistor 44, receives the command in voltage V_{dc} (e.g. 24 volts) defining the control signal to turn IGBT transistors 40a, 15 40b on/off. A resistor 46 is interposed between the gates (G) and the emitters (E) of IGBT transistors 40a, 40b to discharge the current stored in the internal capacitors of the IGBT transistors when these are off. A Zener diode 48 is also interposed between the gates (G) and the 20 emitters (E) of IGBT transistors 40a, 40b to limit the voltage V_{ge} of the IGBT transistors to a predetermined maximum value (e.g. 16 volts).

A recirculating diode is interposed between the collector (C) and emitter (E) of each IGBT transistor to 25 permit current flow during the half-wave opposite that of direct flow through the IGBT transistor (which is a one-way device).

Alternatively, a first and second MOSFET transistor

(not shown) may be used, with the sources (S) connected to each other, and the drains (D) connected respectively to electric line 21 and to an end terminal of respective capacitor 24-27.

5 In the Figure 3 variation, device 1 also defines a variable-inductance inductive element parallel to the variable-capacitance capacitive element.

In the non-limiting embodiment in Figure 3, the variable inductance is defined by a transformer 23 having 10 a primary winding 23a with a number of inputs 50 associated with respective turns and so producing, when selected, different transformation ratios of transformer 23. Inputs 50 are connected selectively to lines 21 and 15 22 on the basis of a control signal from control circuit 30. More specifically, inputs 50 are selected to alter the inductance of the matching circuit, so that the input impedance of matching circuit 7 (i.e. the impedance "seen" by signal generator 3) assumes a value close to an optimum impedance value Z_{opt} (e.g. 50 ohms) to maximize 20 power transfer from generator 3 to inductor 4.
